# $\mathrm{Si}, \mathrm{Al}$ ordering in the double-ring silicate armenite, $\mathrm{BaCa}_{2} \mathrm{Al}_{6} \mathrm{Si}_{9} \mathrm{O}_{30} \mathbf{2} \mathrm{H}_{2} \mathrm{O}$ : A single-crystal X-ray and ${ }^{29}$ Si MAS NMR study 

Thomas Armbruster*<br>Laboratorium für chemische und mineralogische Kristallographie, Universität Bern, Freiestrasse 3, CH-3012 Bern, Switzerland

#### Abstract

The ${ }^{29}$ Si MAS NMR spectrum of armenite from Wasenalp (Valais, Switzerland) indicates complete $\mathrm{Si}, \mathrm{Al}$ ordering. The same chemical shifts ( $-82.3,-95.0$, and -101.8 ppm ) were also measured for armenite from Rémigny (Quebec, Canada), however, the intensity ratios of the NMR bands for the latter sample differed. A full sphere of X-ray single-crystal data on an optically homogeneous domain of armenite from Rémigny was collected on a threecircle diffractometer equipped with a CCD area-detector. The crystal structure was refined in the acentric space group Pnc2 $[a=18.660(2), b=10.697(1) c=13.874(2) \AA]$ to R1 $=3.6 \%$ based on 4275 reflections. These results confirm complete Si, Al ordering. Mean Si-O distances range between 1.615 and $1.629 \AA$; mean Al-O distances between 1.734 and $1.742 \AA$. Calcium is sevenfold coordinated by six framework O atoms and one $\mathrm{H}_{2} \mathrm{O}$ molecule. Barium is 12 -fold coordinated by framework O atoms. Polarized IR spectra in the region of OH absorptions (between 5700 and $1300 \mathrm{~cm}^{-1}$ ) were recorded on polished slabs of Wasenalp armenite and structurally related milarite from Val Giuf. In general, milarite and armenite show similar anisotropy of $\mathrm{H}_{2} \mathrm{O}$ related absorptions.

## Introduction

Armenite, $\mathrm{BaCa}_{2} \mathrm{Al}_{6} \mathrm{Si}_{9} \mathrm{O}_{30} \cdot 2 \mathrm{H}_{2} \mathrm{O}$, named after its first description from the Armen mine, Kongsberg, Norway (Neumann 1941), is a rather rare silicate mineral found in Ba-rich hydrothermal veins or fissures (e.g., Pouliot et al. 1984; Mason 1987; Semenenko et al. 1987; Zak and Obst 1989; Balassone et al. 1989; Senn 1990; Fortey et al. 1991). In hitherto described occurrences armenite displays a complicated twinning pattern and has essentially end-member composition with a constant $\mathrm{Si} / \mathrm{Al}$ ratio of 9/6.
Armenite possesses six-membered double-rings of tetrahedra and is a member of the milarite-group of minerals (Hawthorne et al. 1991). Among this group, armenite has the most pronounced $\mathrm{Al} \leftrightarrow \mathrm{Si}$ substitution, which may be responsible for a deviation from hexagonal symmetry (Armbruster and Czank 1992) observed for most other members of this group. Previous single-crystal X-ray and TEM studies (Armbruster and Czank 1992; Ferraris et al. 1991) indicated that various armenite modifications with variable degrees of $\mathrm{Si}, \mathrm{Al}$ ordering give rise to different super-structures. Recently, Winter et al. (1995) studied the hexagonal structure of the high-temperature synthetic double-ring silicate $\mathrm{BaMg}_{2} \mathrm{Al}_{6} \mathrm{Si}_{9} \mathrm{O}_{30}$, which has the same $\mathrm{Al} / \mathrm{Si}$ ratio as armenite but Ca is replaced by Mg and the synthetic compound is anhydrous.
Milarite, a fissure mineral with the simplified formula $\mathrm{KNa}_{1-x} \mathrm{Ca}_{2}\left(\mathrm{Be}_{3-x} \mathrm{Al}_{x}\right) \mathrm{Si}_{12} \mathrm{O}_{30} \cdot \mathrm{nH}_{2} \mathrm{O}$, shows similar anomalous optical properties as armenite (e.g., Černý et al.

[^0]0003-004X/99/0102-0092\$05.00

1980; Janeczek 1986), which were interpreted to be caused by long range $\mathrm{H}_{2} \mathrm{O}$ ordering (Armbruster et al. 1989).

Two topologically distinct types of tetrahedra exist in the milarite group of minerals: tetrahedra building the double-ring units ( 12 T 1 pfu ) and the ring-connecting tetrahedra ( 3 T 2 pfu ), which alternate with edge-sharing $\mathrm{CaO}_{6}$ octahedra to form twelve-membered rings (Fig. 1). In milarite T1 tetrahedra are occupied by Si only, whereas in armenite Si and Al share T 1 sites (Armbruster and Czank 1992). The T2 tetrahedra in milarite show a mixed Al, Be occupation (e.g., Černý et al. 1980; Armbruster et al. 1989) and in armenite a mixed Si , A1 occupation. O2 connects T1 to six-membered rings, O 1 connects the sixmembered rings to double-ring units, and O 3 connects the double-ring units to T2 tetrahedra thus a tetrahedral framework is formed. Above and below the double-ring units the structural channels are plugged by Ba (armenite) or K (milarite). In armenite (Armbruster and Czank 1992) and milarite (Armbruster et al. 1989) $\mathrm{H}_{2} \mathrm{O}$ occupies structural interstices ( $\mathrm{B}^{\prime}$ sites) close to Ca and increases the Ca coordination from six to seven. Armenite is completely hydrated and has $2 \mathrm{H}_{2} \mathrm{O}$ pfu. Millarite has non-stoichiometric $\mathrm{H}_{2} \mathrm{O} \ll 2$ pfu and additional $\mathrm{Na}, \mathrm{K}$, and Ca may enter the ninefold-coordinated B site, which is 0.7 $\AA$ apart from $\mathrm{B}^{\prime}$.

The cordierite, $\mathrm{Mg}_{2} \mathrm{Al}_{4} \mathrm{Si}_{5} \mathrm{O}_{18}$, and beryl, $\mathrm{Al}_{2} \mathrm{Be}_{3} \mathrm{Si}_{6} \mathrm{O}_{18}$, structures are closely related to double-ring silicates (e.g., Armbruster et al. 1995). Six-membered single-rings in cordierite and beryl are also connected by additional T sites to form a framework. Unfortunately, a different no92

Figure 1. Characteristic portion of the armenite structure (space group Pnc2) showing the tetrahedral double-ring units projected perpendicular to the $c$ axis. Light tetrahedra with dark rims are occupied by Si whereas dark tetrahedra with light rims are occupied by Al. Tetrahedra connecting double-ring units have common edges with $\mathrm{CaO}_{7}$ polyhedra represented by thick black Ca-O bonds. The $\mathrm{H}_{2} \mathrm{O}$ molecule bonded to Ca is shown as medium size sphere. The large sphere is Ba occupying the cage between to adjacent double-ring units. Notice the ordered arrangement of $\mathrm{H}_{2} \mathrm{O}$ molecules either above or below the Ca polyhedron.
menclature (e.g., Cohen et al. 1977) is used for cordierite and beryl where the ring tetrahedra are named T2 and the ring connecting tetrahedra T 1 (just reversed to the nomenclature of double-ring silicates). For a direct comparison between structures with single- and double-sixmembered rings, a standardized labeling is introduced where $\mathrm{T}_{\mathrm{c}}$ designates tetrahedra connecting ring units (single or double) to a tetrahedral framework. $\mathrm{T}_{\mathrm{s}}$ are tetrahedra in single six-membered rings (beryl and cordierite) and $\mathrm{T}_{\mathrm{d}}$ are tetrahedra assembled to six-membered doublerings (e.g., armenite and milarite).

With respect to $\mathrm{Si}, \mathrm{Al}$ ordering, cordierite seems to be an analogue of armenite. In both minerals $T_{s, d}$ and $T_{c}$ tetrahedra may be occupied by Si and Al in a way that Al tetrahedra are always adjacent to Si tetrahedra, in agreement with Loewenstein's (1954) rule. The Al concentration in both minerals corresponds to the maximum value allowed by this Al-avoidance rule. The two available structure refinements on optically untwinned armenites (Ferraris et al. 1991; Armbruster and Czank 1992) were performed on samples from Su Zurfuru, Sardinia, Italy (Balassone et al. 1989) and from Rémigny, Quebec, Canada (Pouliot et al. 1984). Both structures were solved in
the same orthorhombic space group No. 52 (Pnna in standard setting) but led to different Si , Al distributions. Based on T-O distances, armenite from Su Zurfuru has the structural formula $\mathrm{BaCa}_{2}\left[{ }^{[\mathrm{Tc}} \mathrm{Al}_{3}{ }^{\mathrm{Td}}\left(\mathrm{Al}_{3} \mathrm{Si}_{9}\right) \mathrm{O}_{30}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$, whereas armenite from Rémigny has the formula $\mathrm{BaCa}_{2}\left[{ }^{\mathrm{Tc}}\left(\mathrm{Al}_{2} \mathrm{Si}^{\mathrm{Td}}\left(\mathrm{Al}_{4} \mathrm{Si}_{8}\right) \mathrm{O}_{30}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}\right.$. The latter formula can also be obtained by complete $\mathrm{Si}, \mathrm{Al}$ ordering according to Loewenstein's (1954) rule, however, in that case the space group must be lowered to Pnc2 (Armbruster and Czank 1992). Armenite from Sardinia has a statistical $\mathrm{Si}, \mathrm{Al}$ distribution within the $\mathrm{T}_{\mathrm{d}}$ double-ring units leading to a $\mathrm{Si}, \mathrm{Al}$ arrangement that satisfies hexagonal symmetry (Ferraris et al. 1991). The orthorhombic symmetry is caused by displacements of $\mathrm{CaO}_{6}$ octahedra and neighboring water molecules (Ferraris et al. 1991). In the Pnna refinement model for the sample from Canada (Armbruster and Czank 1992) well-ordered Si , Al clusters alternate with $\mathrm{Si}, \mathrm{Al}$ disordered $\mathrm{T}_{\mathrm{c}}$ and $\mathrm{T}_{\mathrm{d}}$ tetrahedra. The presence of both $\mathrm{Si}, \mathrm{Al}$ ordered and disordered clusters within the same structure was considered highly unusual (Armbruster and Czank 1992). The question thus arouses whether the optically homogeneous crystal fragment from Rémigny was composed of completely ordered submicroscopic domains in a twin relationship or whether the strong pseu-do-hexagonal symmetry led to correlation problems prohibiting a refinement of a completely $\mathrm{Si}, \mathrm{Al}$ ordered model. The structure of the synthetic double-ring silicate, $\mathrm{BaMg}_{2} \mathrm{Al}_{6} \mathrm{Si}_{9} \mathrm{O}_{30}$, is truly hexagonal (space group $P 6 / m c c$ ) with a $\mathrm{Si} / \mathrm{Al}$ ratio of $3 / 1$ in the six-membered double-rings (statistically distributed) and only Al in the tetrahedra connecting the double-rings to a framework (Winter et al. 1995). Thus, $\mathrm{Si}, \mathrm{Al}$ ordering in this sample is the same as in armenite from Sardinia (Ferraris et al. 1991).

A similar relationship to that between the tetrahedral frameworks of cordierite and armenite exists between beryl and milarite. In the latter pair of minerals, $\mathrm{T}_{\mathrm{s}}$ and $\mathrm{T}_{\mathrm{d}}$ tetrahedra are occupied by only Si whereas $\mathrm{T}_{\mathrm{c}}$ tetrahedra are Be-rich.

One aim of the present study is to determine $\mathrm{Si}, \mathrm{Al}$ ordering in armenite by ${ }^{29} \mathrm{Si}$ MAS NMR spectroscopy. This technique is powerful in distinguishing $\mathrm{SiO}_{4}$ clusters with chemically different adjacent tetrahedra. In previous ${ }^{29} \mathrm{Si}$ MAS NMR studies on Si , Al-ordering in cordierite (Putnis et al. 1985; Hölscher and Schreyer 1989; Senegas et al. 1991) $\mathrm{T}_{\mathrm{s}}(\mathrm{Si})$ tetrahedra with $1,2,3$, and 4 adjoining $\mathrm{AlO}_{4}$ tetrahedra could be resolved leading to four different ${ }^{29} \mathrm{Si}$ NMR chemical shifts. In addition $\mathrm{T}_{\mathrm{s}}$ tetrahedra could be distinguished from $\mathrm{T}_{\mathrm{c}}$ tetrahedra.

If we assume complete $\mathrm{Si}, \mathrm{Al}$ ordering in armenite according to Loewenstein's (1954) rule, four $\mathrm{T}_{\mathrm{d}}(\mathrm{Si})$ tetrahedra pfu corner-linked with two $\mathrm{AlO}_{4}$ and two $\mathrm{SiO}_{4}$ tetrahedra $(2 \mathrm{Al}, 2 \mathrm{Si})$ and additional four $\mathrm{T}_{\mathrm{d}}(\mathrm{Si})$ tetrahedra pfu corner-linked with three $\mathrm{AlO}_{4}$ and one $\mathrm{SiO}_{4}$ tetrahedra ( $3 \mathrm{Al}, 1 \mathrm{Si}$ ) should be resolved. In addition, one $\mathrm{T}_{\mathrm{c}}(\mathrm{Si})$ tetrahedron is surrounded by four $\mathrm{AlO}_{4}$ tetrahedra ( 4 Al ). Milarite has $12 \mathrm{~T}_{\mathrm{d}}(\mathrm{Si})$ tetrahedra connected to either $(1 \mathrm{Be}, 3 \mathrm{Si})$ or $(1 \mathrm{Al}, 3 \mathrm{Si})$. For a better assignment of the chemical shifts in the armenite ${ }^{29} \mathrm{Si}$ MAS NMR spectra
and for comparison with beryl and cordierite literature data, additional spectra of milarite are needed.

Furthermore, the development of a new generation of X-ray detectors based on the CCD chip enables fast collection of precise single-crystal data. A rough estimate indicates that for a successful refinement of armenite in space group $P n c 2$ a full sphere of diffraction data should be collected. This yields ca. 20000 reflections up to $\theta=$ $25^{\circ}$ where each reflection should be scanned for 3 to 5 min to obtain the required accuracy. With a conventional diffractometer such a measurement would require about two months. In contrast, essentially the same experiment using a CCD-type area detector can be conducted within one day.

Because the oxygen positions of the $\mathrm{H}_{2} \mathrm{O}$ molecules in armenite and milarite are very similar (Armbruster et al. 1989; Armbruster and Czank 1992) and the $\mathrm{H}_{2} \mathrm{O}$ arrangement is believed to be one of the sources of anomalous optical properties in milarite, the other aim of this study is a comparison of $\mathrm{H}_{2} \mathrm{O}$ orientations in armenite and milarite applying single-crystal FTIR spectroscopy. It is expected that the different $\mathrm{Si} / \mathrm{Al}$ ratio in the framework of armenite and milarite leads also to different orientations of the $\mathrm{H}-\mathrm{H}$ vectors of $\mathrm{H}_{2} \mathrm{O}$ molecules in both minerals, although the position of the $\mathrm{H}_{2} \mathrm{O}$ oxygen site is very similar.

## Experimental methods

## Sample selection

The previous study of armenite (Armbruster and Czank 1992) left open questions about $\mathrm{Si}, \mathrm{Al}$ ordering and $\mathrm{H}_{2} \mathrm{O}$ arrangement in armenite from Rémigny, Quebec, Canada (Pouliot et al. 1984) and from Wasenalp, Valais, Switzerland (Senn 1990). Both samples have a constant Si/Al ratio of $9 / 6$ but different superstructures. An additional reason for selecting these two samples is the availability of sufficient material for MAS NMR spectroscopy.

The milarites studied for comparison were selected because crystal structure refinements and chemical analyses were already published for these samples (Černý et al. 1980; Armbruster et al. 1989) and because material of sufficient quality and quantity was available. Milarite from Val Giuf, Graubünden, Switzerland, has the composition $\mathrm{K}_{1.15} \mathrm{Na}_{0.05} \mathrm{Ca}_{2.09} \mathrm{Al}_{0.63} \mathrm{Be}_{2.37} \mathrm{Si}_{12} \mathrm{O}_{30} \cdot 0.6 \mathrm{H}_{2} \mathrm{O}$ (Armbruster et al. 1989), and the one from Rössing, Namibia, has the composition $\mathrm{K}_{1.10} \mathrm{Na}_{0.16} \mathrm{Ca}_{2.00} \mathrm{Mn}_{0.02} \mathrm{Al}_{0.66} \mathrm{Be}_{2.34} \mathrm{Si}_{12} \mathrm{O}_{30}$ $\cdot 0.77 \mathrm{H}_{2} \mathrm{O}$ (Černý et al. 1980).

## ${ }^{29}$ Si MAS NMR

Four samples were studied. (1) a hand-picked concentrate of armenite from Rémigny, Quebec, Canada (Pouliot et al. 1984). Due to the small amount of sample available, the armenite powder was diluted with KBr . (2) A powder of armenite from Wasenalp, Valais, Switzerland, was ground from a crystal fragment about 1 cm in diameter (provided by Andres Martin). (3) Three transparent sin-gle-crystals of milarite from Val Giuf, Switzerland, were crushed to a powder. (4) A powder was prepared from
one greenish translucent crystal of milarite from Rössing, Namibia. All samples were checked by Guinier X-ray photographs prior to NMR to ensure that no other silicate phases were admixed.

The milarite spectra were measured in their natural state and after dehydration 24 h at $800{ }^{\circ} \mathrm{C}$. All NMR spectra were recorded at room temperature at 59.6 MHz (spinning rate 2770 Hz ) on a Bruker MSL300 NMR spectrometer (courtesy of A. Sebald and L. Merwin, Bayreuth, Germany). Recycle delays were varied between 10 and 60 s . The spectra (Fig. 2) were collected with recycle delays of 30 s and pulse duration of $2.5 \mu \mathrm{~s}$ corresponding to a $40^{\circ}$ flip angle. Typically between 900 and 2800 transients were accumulated. No line broadening or base line corrections were applied. Isotropic chemical shifts $\delta\left({ }^{29} \mathrm{Si}\right)$ are given relative to $\delta\left({ }^{29} \mathrm{Si}\right) \mathrm{Si}\left(\mathrm{CH}_{3}\right)_{4}=0 \mathrm{ppm}$ as the external reference; $\delta\left({ }^{29} \mathrm{Si}\right)$ values are accurate within $\pm 0.1 \mathrm{ppm}$.

## Single-crystal X-ray data collection and refinement

The same crystal from Rémigny (Quebec, Canada) as used by Armbruster and Czank (1992) was reinvestigated in this study. An optically homogeneous crystal disk ( 0.075 mm thick and 0.200 mm in diameter) was separated from a thin section by the microscopic milling technique (Medenbach 1986) and mounted on a three-circle Siemens SMART system equipped with a CCD area detector. Details of the data collection are summarized in Table 1. Data reduction including Lorentz and polarization corrections were performed with the program SAINT (Siemens 1996). An empirical absorption correction based on $\psi$-scans was applied, which reduced the internal R value from 5.12 to $3.96 \%$. The structure was solved and refined (program SHELXL93 by Sheldrick 1993) in space group Pnc2 leading to pronounced correlations ( $<89 \%$ ) between atoms related by a pseudo-center of symmetry. Nevertheless, the refinements converged with individual isotropic displacement parameters for all T and O sites. A centrosymmetric refinement (space group Pnna) of data collected on the same crystal with a conventional X-ray detector has been reported by Armbruster and Czank (1992). This model yielded substantial Si, Al disorder.

Based on T-O distances Si and Al scattering curves were assigned. Highest peaks in the final difference Fourier maps were 1.45 and $-1.2 \mathrm{e} / \mathrm{A}^{3}$. Positive peaks are between Ca and coordinating O . The absolute structure could be determined without any indication of twinning by the pseudo-center of symmetry. This is confirmed by the low absolute structure parameter $\mathrm{x}=0.07$ (2) (Flack 1983). Tetrahedral $\mathrm{T}_{\mathrm{c}}$ and $\mathrm{T}_{\mathrm{d}}$ sites, and O1, O2, and O3 were labeled as described above where the additionally affixed characters are arbitrary tags for identification. An Al or Si at the end of the T label indicates whether the tetrahedron is occupied by Al or Si . W1 and W2 are the O positions of the $\mathrm{H}_{2} \mathrm{O}$ molecules.

Figure 2. ${ }^{29}$ Si MAS NMR spectra of double-ring silicates. (a) Milarite from Val Giuf (Switzerland); (b) milarite from Rössing (Namibia); (c) armenite from Wasenalp (Switzerland); (d) armenite from Rémigny (Canada).

## Single-crystal FTIR spectroscopy

Thin, doubly polished slabs were used for IR spectroscopy. Armenite from Wasenalp, Valais, Switzerland, was available in large (centimeter sized) pseudo-hexagonal prismatic crystals. Sections perpendicular to the pseudohexagonal $c$ axis showed sectors and lamellae with strongly undulatory extinction under the polarizing microscope (crossed polarizers). One section perpendicular
to the pseudo-hexagonal $c$ axis was 0.038 mm thick, whearas another section parallel to the pseudo-hexagonal $c$ axis was 0.050 mm thick. Milarite from Val Giuf, Switzerland was prepared as a 0.122 mm thick slab parallel to [001]. All spectra were recorded on a PERKIN ELMER 1760X FT-IR spectrometer (courtesy of A. Beran and E. Libowitzky, Universität Wien, Austria). The measuring spot was limited to 1 mm by a field aperture. In-

tensities were collected with a liquid nitrogen cooled MCT detector. Polarized spectra were measured parallel and perpendicular to the pseudo-hexagonal $c$-axis between 5700 and $1300 \mathrm{~cm}^{-1}$ at a resolution of $4 \mathrm{~cm}^{-1}$. In addition, the armenite slab, cut perpendicular to the pseu-do-hexagonal $c$-axis, was measured at different polarizer orientations. Each of the spectra was averaged from 100 single measurements to minimize the background noise. Due to the sample thickness and high $\mathrm{H}_{2} \mathrm{O}$ concentration,
some very strong absorptions did not transmit light at band center.

## Results

## ${ }^{29}$ Si MAS NMR

Both milarites show only one strongly broadened band of Lorentzian peak shape assigned to $\mathrm{T}_{\mathrm{d}}$ tetrahedra (Fig. 2, Table 2). For the Val Giuf sample the band is at -104.8 ppm. The milarite from Rössing, Namibia, displays the band at -104.3 ppm . After 24 h heat treatment at $800^{\circ} \mathrm{C}$ the band remains broad and is centered at 104.5 ppm . There is no indication of Si on $\mathrm{T}_{\mathrm{c}}$.

Both armenites have ${ }^{29}$ Si MAS NMR characterized by three bands at about $-82.5,-95.0$, and -101.6 ppm (Fig. 2, Table 2). However, the relative intensities of these bands differ significantly between these two samples. In the Wasenalp armenite, the bands at -95.0 and -101.6 ppm are approximately of equal size and the -82.5 band has about $1 \frac{1}{4}$ intensity of the former two. In the Rémigny armenite the intensity distribution is $6 \%$ at $-82.5,59 \%$ at -95.0 , and $35 \%$ at -101.6 ppm . Intensities were estimated by multiplying the peak half-width by the height.

## Structure refinement

Atomic coordinates are in Table 3, and selected interatomic distances are summarized in Table 4. The Pnc 2 structure yielded 12 symmetry independent $\mathrm{T}_{\mathrm{d}}$ (all on general positions) and $5 \mathrm{~T}_{\mathrm{c}}$ sites (only one on a general position). Mean T-O distances cluster in two groups, one group with T-O distances between 1.615 and $1.629 \AA$, the other group with T-O distances between 1.734 and 1.742 $\AA$. The tetrahedra with short T-O distances were assigned to Si , those with long T-O distances to Al. The arrangement of Si and Al is in agreement with the Loewenstein's (1954) rule. There are four $\mathrm{T}_{\mathrm{d}}$ and three $\mathrm{T}_{\mathrm{c}}$ sites filled with Al , thus Si and Al are completely ordered in the investigated armenite crystal. A partially occupied (11\%) position labeled CC occurred at the cage center of the

[^1]six-membered double-rings that was assigned to $\mathrm{H}_{2} \mathrm{O}$. It locally increases the Ba coordination from 12 to 14 . This $\mathrm{H}_{2} \mathrm{O}$ site is $3.28(6) \AA$ from two neighboring Ba positions. Completely occupied $\mathrm{H}_{2} \mathrm{O}$ sites (W1 and W2) increase the Ca coordination from sixfold to sevenfold. The distribution of W1 and W2 associated with the related structural distortions are responsible for the primitive lattice. The completely ordered $\mathrm{Si}, \mathrm{Al}$ arrangement in the tetrahedral framework fulfills requirements of a $C$-centered lattice (Fig. 3). Both, Si , Al ordering and $\mathrm{H}_{2} \mathrm{O}$ distribution are responsible for deviation from hexagonal symmetry.

## Single-crystal FTIR spectroscopy

The absorption bands and approximate intensities with polarizations parallel and perpendicular to the pseudohexagonal $c$ axis are listed in Table 5 and shown in Figure 4. In general milarite and armenite show much stronger anisotropy of $\mathrm{H}_{2} \mathrm{O}$ related absorption bands than armenite. The band assignments were adopted from Hawthorne et al. (1991).

## Discussion

## ${ }^{29}$ Si NMR MAS spectroscopy

In the crystal structure of milarite (e.g., Armbruster et al. 1989; Hawthorne et al. 1991) each Si tetrahedron is connected to three additional ring $\mathrm{SiO}_{4}$ tetrahedra $\left(\mathrm{T}_{\mathrm{d}}\right)$ and, in addition, to one Be or Al tetrahedron ( $\mathrm{T}_{\mathrm{c}}$ ) interconnecting the $\mathrm{Si}_{12} \mathrm{O}_{30}$ double-rings. Si with neighboring Be amounts to $73-79 \%$, the remaining Si is linked to Al . Thus in the ${ }^{29} \mathrm{Si}$ MAS NMR spectra one should expect one weak peak for $\mathrm{T}_{\mathrm{d}}(3 \mathrm{Si}, 1 \mathrm{Al})$ and one strong peak for $\mathrm{T}_{\mathrm{d}}(3 \mathrm{Si}, 1 \mathrm{Be})$. The spectra, however, indicate only one broad band. From this observation we must assume that ( $3 \mathrm{Si}, 1 \mathrm{Al}$ ) and ( $3 \mathrm{Si}, 1 \mathrm{Be}$ ) lead to very similar chemical shifts thus the two band structure cannot be resolved. For synthetic cordierite of composition $\left.\mathrm{Mg}_{2}\left(\mathrm{Al}_{2} \mathrm{Be}\right)\right) \mathrm{Si}_{6} \mathrm{O}_{18}$, Hölscher and Schreyer (1989) observed three ${ }^{29} \mathrm{Si}$ MAS NMR bands assigned to $\mathrm{Si}(2 \mathrm{Si}, 2 \mathrm{Al}), \mathrm{Si}(2 \mathrm{Si}, 1 \mathrm{Be}, 1 \mathrm{Al})$, and $\mathrm{Si}(2 \mathrm{Si}, 2 \mathrm{Be})$ at -106.2 and -103.9 , and -101.6 , respectively. However, in this Be-substituted cordierite Si is always adjacent to two additional Si and not to three Si tetrahedra as in the double-ring silicate milarite. In beryls of the composition $\mathrm{Al}_{2}\left(\mathrm{Be}_{3-x} \mathrm{Li}_{x}\right) \mathrm{Si}_{6} \mathrm{O}_{18}[\mathrm{Cs}, \mathrm{Li}, \mathrm{Na}, \mathrm{K}]_{x}$ with $x<0.45$, Sherriff et al. (1991) observed only one ${ }^{29} \mathrm{Si}$ MAS NMR band that broadened with increasing $x$. Beryl has the same tetrahedral topology as cordierite and each Si is adjacent to two $\mathrm{T}_{5} \mathrm{SiO}_{4}$ tetrahedra plus two $\mathrm{T}_{\mathrm{c}}$ $(\mathrm{Be}, \mathrm{Li}) \mathrm{O}_{4}$ connecting the rings to a tetrahedral framework. The broadening of the milarite ${ }^{29} \mathrm{Si}$ MAS NMR band has probably similar disorder reasons as reported for beryl: (1) the observed band is a mixture between $\mathrm{Si}(3 \mathrm{Si}, \mathrm{Be})$ and $\mathrm{Si}(3 \mathrm{Si}, \mathrm{Al})$; or (2) milarite possesses a disordered and distorted structure because B type interstices are either vacant or occupied by $\mathrm{Na}, \mathrm{K}, \mathrm{Ca}$, or $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{Al}, \mathrm{Be}$ are disordered on $\mathrm{T}_{\mathrm{d}}$. According to Sherriff et al. (1991), such disorder may lead to substitutional MAS NMR broadening. The effect of $\mathrm{H}_{2} \mathrm{O}$ is not significant because the broadening remained after dehydration. (3) For the milarite from Rössing, paramagnetic elements ( $<0.15 \mathrm{wt} \% \mathrm{MnO}$ ) were analyzed (Černý et al. 1980), which are probably responsible for the characteristic Lorentzian peak shape of the milarite spectra. A similar line shape is observed for the Val Giuf sample. Thus we may speculate that low concentrations of Fe and/or Mn are also present in this sample, although electron microprobe analyses (Černý et al. 1980; Armbruster et al. 1989) failed to detect significant Fe and/or Mn concentrations. Low concentrations of paramagnetic elements (lower than resolved from routine electron microprobe analyses) are

sufficient to cause substantial peak broadening (e.g., Kirkpatrick 1988).

The fully ordered structure model of armenite (Figs. 1 and 3 ) refined in this paper leads to $44.44 \% \mathrm{~T}_{\mathrm{d}}(\mathrm{Si}, 3 \mathrm{Al})$, $44.44 \% \mathrm{~T}_{\mathrm{d}}(2 \mathrm{Si}, 2 \mathrm{Al})$, and $11.11 \% \mathrm{~T}_{\mathrm{c}}(4 \mathrm{Al})$. It is known that ring connecting tetrahedra ( $\mathrm{T}_{\mathrm{c}}$ ) in cordierite show more positive ${ }^{29} \mathrm{Si}$ MAS NMR chemical shifts than ring tetrahedra ( $\mathrm{T}_{\mathrm{s}}$ ) and can thus be distinguished (e.g., Putnis et al. 1985; Hölscher and Schreyer 1991). The three MAS NMR bands observed for Wasenalp armenite agree in intensity and relative chemical shifts with a fully ordered $\mathrm{Si}, \mathrm{Al}$ distribution in agreement with Loewenstein's rule. The line at -82.3 is assigned to $\mathrm{T}_{\mathrm{c}}(4 \mathrm{Al})$, and the lines at -95.0 and at -101.6 to $\mathrm{T}_{\mathrm{d}}(\mathrm{Si}, 3 \mathrm{Al})$ and $\mathrm{T}_{\mathrm{d}}(2 \mathrm{Si}, 2 \mathrm{Al})$, respectively. These $\mathrm{T}_{\mathrm{d}}$ lines are shifted to significantly more positive values compared to the $\mathrm{T}_{\mathrm{s}}$ lines of cordierite ( -101.3 and -106.4 ) with the same assignment (e.g., Hölscher and Schreyer 1991), whereas the $\mathrm{T}_{\mathrm{c}}(4 \mathrm{Al})$ line for cordierite is at -79.5 . In double-ring silicates, $\mathrm{T}_{\mathrm{d}}$ tetrahedra are linked to three additional $\mathrm{T}_{\mathrm{d}}$ tetrahedra and one $T_{c}$ tetrahedron. This leads for armenite to an average $\mathrm{T}_{\mathrm{d}}-\mathrm{O}-\mathrm{T}$ angle of ca. $145^{\circ}$. In cordierite and beryl, $\mathrm{T}_{\mathrm{s}}$ tetrahedra have two $T_{s}$ and two $T_{c}$ neighbors leading to an average $\mathrm{T}_{\mathrm{s}}-\mathrm{O}-\mathrm{T}$ angle of $151^{\circ}$. Radeglia and Engelhardt
(1985) have shown that the average T-O-T angle at the ${ }^{29} \mathrm{Si}$ atom is correlated with the NMR chemical shift, which agrees qualitatively for cordierite and armenite. The $\mathrm{T}_{\mathrm{c}}(4 \mathrm{Al})$ tetrahedron in Mg cordierite $\left(\mathrm{T}_{\mathrm{c}}-\mathrm{O}-\mathrm{T}_{\mathrm{s}}\right.$ angle $=132.5^{\circ}$ ) has, in addition, two edge-sharing $\mathrm{MgO}_{6}$ octahedra (e.g., Cohen et al. 1977), whereas $\mathrm{T}_{\mathrm{c}}(4 \mathrm{Al})$ tetrahedra in armenite (average $\mathrm{T}_{\mathrm{c}}-\mathrm{O}-\mathrm{T}_{\mathrm{d}}$ angle $=130^{\circ}$ ) have two edge-sharing $\mathrm{CaO}_{7}$ polyhedra. According to the group-electronegativity concept of Janes and Oldfield (1985), the chemical shift of armenite $\mathrm{T}_{\mathrm{c}}$ tetrahedra should be more negative than the one of cordierite $\mathrm{T}_{\mathrm{c}}$ tetrahedra, which also agrees with the observation (Table 2).

The Rémigny armenite has ${ }^{29}$ Si MAS NMR bands that agree in their position with those of an ordered structure (e.g.,Wasenalp armenite), however the intensity ratios are significantly different thus either a more complicated Si , Al distribution pattern or a mixture between various Si , Al ordered variants must be assumed. Pouliot et al. (1984) report that optically biaxial armenite from Rémigny is intermixed with uniaxial domains. The uniaxial crystals occur as individuals and as euhedral core within larger twinned crystals. Ferraris et al. (1991) found a hexagonal $\mathrm{Si}, \mathrm{Al}$ arrangement for armenite from Sardinia where all

Figure 3. Polyhedral representation of the $P n c 2$ armenite structure projected parallel to $c$ with unit-cell outlines. Ba is not shown, small spheres are $\mathrm{H}_{2} \mathrm{O}$ molecules completing $\mathrm{CaO}_{6}$ octahedra to sevenfold Ca coordination. Notice the ordered arrangement of $\mathrm{H}_{2} \mathrm{O}$ molecules. Where $\mathrm{H}_{2} \mathrm{O}$ is not situated above the $\mathrm{CaO}_{6}$ octahedron it is hidden below the octahedron. Si occupies light tetrahedra with black rims; Al occupies dark tetrahedra with light rims.
$\mathrm{T}_{\mathrm{c}}$ tetrahedra are occupied by Al and the twelve $\mathrm{T}_{\mathrm{d}}$ tetrahedra are filled with nine Si and three Al in a disordered fashion. Admixture of this armenite modification is in agreement with the decreased intensity of the $\mathrm{T}_{\mathrm{c}}(4 \mathrm{Al})$ line at -82.3 , but various arrangements of the remaining Al in $\mathrm{T}_{\mathrm{d}}$ tetrahedra lead inevitably to local $\mathrm{T}_{\mathrm{d}}(3 \mathrm{Si}, \mathrm{Al})$ units for which no lines were observed in the Rémigny spectrum. In addition, the Ferraris et al. (1991) model would yield high concentrations of $\mathrm{T}_{\mathrm{d}}(2 \mathrm{Si}, 2 \mathrm{Al})$ and only low amounts of $\mathrm{T}_{\mathrm{d}}(1 \mathrm{Si}, 3 \mathrm{Al})$, contrary to the observed spectrum. If we calculate an average structural formula for the Rémigny armenite on the basis of the $\mathrm{T}_{\mathrm{d}}, \mathrm{T}_{\mathrm{c}}{ }^{29} \mathrm{Si}$ MAS NMR intensities, we obtain $\mathrm{BaCa}_{2}\left(\mathrm{Si}_{0.54} \mathrm{Al}_{2.46}\right)\left(\mathrm{Si}_{8.46} \mathrm{Al}_{3.54}\right)$ $\mathrm{O}_{30} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ but we are not able to develop a convincing structural model which is in agreement with a stoichiometric Si/Al ratio of 9/6 (Pouliot et al. 1984), the arrangement of tetrahedra in double-ring silicates, and the observed MAS NMR spectrum.

## Structural modifications of armenite

For cordierite two extreme modifications are known, hexagonal high cordierite with random $\mathrm{Si}, \mathrm{Al}$ distribution in the ring tetrahedra, and $C$-centered orthorhombic low cordierite with a fully ordered $\mathrm{Si}, \mathrm{Al}$ arrangement. The same holds for armenite. The Si , Al disordered modification (Ferraris et al. 1991), however, is not hexagonal as are milarite (Armbruster et al. 1989), synthetic $\mathrm{BaMg}_{2} \mathrm{Al}_{6} \mathrm{Si}_{9} \mathrm{O}_{30}$ (Winter et al. 1995), and high cordierite but orthorhombic (space group Pnna), due to the ordered arrangement of $\mathrm{H}_{2} \mathrm{O}$ molecules that imposes additional strain on the structure. The $\mathrm{Si}, \mathrm{Al}$ ordered armenite modification, as exemplified by the present single-crystal X-

Figure 4. Polarized FTIR absorption spectra of (a) armenite and (b) milarite. For better visibility the $E \perp c$ spectra are vertically offset by 0.5 . Due to very strong absorption, bands around 3500 and $1600 \mathrm{~cm}^{-1}$ are truncated.
ray data of Rémigny armenite, may adopt $P n c 2$ symmetry. The $\mathrm{Si}, \mathrm{Al}$ ordering pattern, however, yields a $C$-centered distribution similar to low-cordierite. X-ray reflections with $h+k \neq 2 n$ are caused by the arrangement of $\mathrm{H}_{2} \mathrm{O}$ molecules and imposed structural distortions. Other ordered $\mathrm{H}_{2} \mathrm{O}$ arrangements may lead to different space groups or other translational symmetries as observed for the Wasenalp armenite (Armbruster and Czank 1992). Various $\mathrm{H}_{2} \mathrm{O}$ arrangements can be obtained by ordered shifts of the $\mathrm{H}_{2} \mathrm{O}$ oxygen site either above or below the center of the B cavity. Thus diffuse reflections of the type $h+k \neq 2 n$ are indicative for partial $\mathrm{H}_{2} \mathrm{O}$ disorder.

## $\mathrm{H}_{2} \mathrm{O}$ orientation in milarite

Idealized milarite has the formula $\mathrm{KCa}_{2}\left(\mathrm{Be}_{2} \mathrm{Al}^{2}\right) \mathrm{Si}_{12} \mathrm{O}_{30}$. $\mathrm{nH}_{2} \mathrm{O}$. However, many natural samples possess an excess of Be and a deficit of Al , which is charge balanced by alkali and alkali earth cations, positioned at the B site (Černý et al. 1980). The B site represents a ninefoldcoordinated cavity between two octahedral positions parallel to the $c$ axis. Cations on the B site prefer the center of the cavity whereas non-stoichiometric $\mathrm{H}_{2} \mathrm{O}$ is displaced parallel to $c$ (Armbruster et al. 1989) and has six nearest oxygen neighbors ( $3 \times \mathrm{O} 1$ and $3 \times \mathrm{O} 3$ ). Calcium octahedra in such an idealized milarite are edge-linked with three $T_{c}$ tetrahedra, where locally two $T_{c}$ tetrahedra are occupied by Be and one by Al. This local arrangement reduces the observed 3 average symmetry of Ca . In addition, O 3 coordinating Ca is corner linked with a $\mathrm{T}_{\mathrm{d}}(\mathrm{Si})$ tetrahedron. Depending on whether O3 links a Be or an Al tetrahedron, the Pauling bond strength of O 3 is either one $5 / 6$ (underbonded) or one 13/12 (overbonded). Ow is $2.867 \AA$ from O3 and $2.813 \AA$ from O1 (Armbruster et al. 1989). O1 has an ideal Pauling bond strength of 2.0 because it connects two $\mathrm{T}_{\mathrm{d}}(\mathrm{Si})$ tetrahedra. Thus from the view of bond strength, O3 (partially underbonded) is the favorable O to accept a hydrogen bond from Ow. Steric constraints, however, exclude a $\mathrm{H}_{2} \mathrm{O}$ proton oriented toward O3 because of short $\mathrm{H}-\mathrm{Ca}$ distances. The most favorable $\mathrm{H}_{2} \mathrm{O}$ proton arrangement is obtained by bifurcated hydrogen bonds to O 1 and O 3 with $\mathrm{H} 1(0.319,0.749$, $0.065)$ and $\mathrm{H} 2(0.241,0.579,0.065)$. In addition, this proton arrangement is either statically or dynamically disordered governed by the three-fold axis passing through Ow. This model has the H-H vector in (001) and is also in agreement with the polarization of the $\nu_{2} \nu_{3}$ combination and the $\nu_{3}$ asymmetric stretch mode observed in our IR spectra and those of Hawthorne et al. (1991). In the above model the diad of the $\mathrm{H}_{2} \mathrm{O}$ molecule is inclined by about $66^{\circ}$ to the $c$ axis of milarite. A stronger hydrogen bond to O 1 decreases the inclination of the $\mathrm{H}_{2} \mathrm{O}$ diad. Our IR spectra and those of Hawthorne at al. (1991) show no polarization for the $\nu_{1}$ mode and incomplete polarization for the $\nu_{2}$ mode. The polarization of the modes $\nu_{1}$ and $\nu_{2}$ determine the orientation of the diad of the $\mathrm{H}_{2} \mathrm{O}$ molecule. However, the $v_{1}, v_{2}, v_{3}$ band assignments of $\mathrm{H}_{2} \mathrm{O}$ vibrations suggested by Hawthorne et al. (1991) and adopted

Figure 5. Polyhedral represenation of the $\mathrm{H}_{2} \mathrm{O}$ environment in armenite. The sphere represents W 1 positioned on a pseudothreefold axis (parallel to $c$ ); bonds are drawn to the six closest O neighbors $(3 \times \mathrm{O} 3$ and $3 \times \mathrm{O} 1)$. The $\mathrm{CaO}_{6}$ octahedron below shares O3 type edges with $\mathrm{T}_{\mathrm{c}}$ tetrahedra. Four-membered rings of $\mathrm{T}_{\mathrm{d}}$ tetrahedra (seen edge-wise) are fragments of the doublering units. Si occupies light tetrahedra with black rims; Al occupies dark tetrahedra with light rims. The $\mathrm{H}_{2} \mathrm{O}$ molecule is slghtly shifted toward the O1-type O atoms connecting an $\mathrm{SiO}_{4}$ and an $\mathrm{AlO}_{4} \mathrm{~T}_{\mathrm{d}}$ tetrahedron.
in the above model are problematic because $\nu_{1}$ and $\nu_{2}$ should show the same polarization (not observed). Thus the assumption of a "symmetric" $\mathrm{H}_{2} \mathrm{O}$ molecule is questionable. More probable is a $\mathrm{H}_{2} \mathrm{O}$ molecule with one "free" OH vector leading to the $\sim 3600 \mathrm{~cm}^{-1}$ absorption and another with a medium strong hydrogen bond causing the $\sim 3500 \mathrm{~cm}^{-1}$ absorption. A more detailed discussion of the exact $\mathrm{H}_{2} \mathrm{O}$ orietation is hampered by the fact that milarite crystals show parallel to (001) anomalous optical properties (e.g., sectoring), indicating symmetry lowering. Thus a hexagonal model is not appropriate to derive detailed $\mathrm{H}_{2} \mathrm{O}$ orientations.

## $\mathrm{H}_{2} \mathrm{O}$ orientation in armenite

Figure 5 shows the local environment of W1 in a completely $\mathrm{Si}, \mathrm{Al}$ ordered armenite, as derived from the ${ }^{29} \mathrm{Si}$ MAS NMR spectra of the Wasenalp sample and the present $P n c 2$ structure refinement. There are three O3 type O atoms (O37, O312, and O310) close to W1 (ca. $2.9 \AA$ apart) and participating in $\mathrm{Ca}-\mathrm{O}$ bonds. These O 3 type O atoms connect an Si tetrahedron and an Al tetrahedron with Ca and are slightly overbonded. W1 is additionally coordinated by three O1 type O atoms (O14, O11, and O 12 ) with O 14 and O 11 connecting Si and Al tetrahedra whereas O12 links two Si tetrahedra. Thus the slight underbonding of O14 and O11 makes those O atoms pre-
ferred acceptors of weak hydrogen bonds. This is also confirmed by the position of W1, which is $2.759 \AA$ from O 14 and $2.941 \AA$ from O11 but $3.149 \AA$ from O12. This would cause the $\mathrm{H}-\mathrm{H}$ vector to be almost parallel to pseu-do-hexagonal ( 001 ) which is not supported because the single-crystal IR-spectra show no significant polarization for $v_{2} v_{3}$ and $v_{3}$ modes. The spectra support a $\mathrm{H}_{2} \mathrm{O}$ model where one proton is hydrogen bonded to the closest O14 with the second proton rotationally disordered. A similar situation is found around W2 where O16 and O13 have distances of $2.793 \AA$ and $2.821 \AA$ to W2.
