#### Abstract

Synthetic crystals of melanotekite and kentrolite were obtained at $850^{\circ} \mathrm{C}$ from melt. The aluminum analogue of kentrolite $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ was hydrothermally synthesized at $2 \mathrm{GPa}, 650^{\circ} \mathrm{C}$ together with zoisite $-(\mathrm{Pb})$ and margarite- $(\mathrm{Pb})$. Synthesis products were characterized by single-crystal diffraction studies and microprobe analysis.

The aluminum analogue $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ was observed in space group $P b c n$ with lattice parameters $a=6.8981(7) \AA, b=10.6906(15) \AA, c=9.7413(10) \AA$, and $V=718.37 \AA^{3}$. Fourier mappings show no irregularities of the Pb site.

Melanotekite with lattice parameters $a=6.9786(6) \AA, b=11.0170(11) \AA, c=10.0895(9) \AA$, and $V=775.71(17) \AA^{3}$ in space group $P b c n$ show a slightly deformed Pb -position in Fourier mappings.

Kentrolite was observed in space group $P 2_{1} 22_{1}$ with pseudo-symmetry to $P b c n$ with lattice parameters $a=7.0103(5) \AA, b=11.0729(7) \AA, c=9.9642(7) \AA$, and $V=773.47(11) \AA^{3}$. Fourier mappings of the kentrolite structure show that two different split Pb sites exist, which causes lower symmetry. The unit-cell volume of different members of the kentrolite group is a linear function of trivalent ionic radii in sixfold coordination for the elements $\mathrm{Al}, \mathrm{Ga}$, In , and also for Fe and Mn in high spin mode.

The structure of $\mathrm{Pb}_{2} \mathrm{M}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}\left(\mathrm{M}=\mathrm{Al}^{3+}, \mathrm{Fe}^{3+}, \mathrm{Mn}^{3+}\right)$ is built on isolated M -octahedra chains parallel $\mathbf{c}$, M-octahedra sharing alternately trans and skew edges. Each $\mathrm{Si}_{2} \mathrm{O}_{7}$-group is linked with their vertices to three octahedra chains. Their $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ bond angles depend on the size of M -octahedra and are $129.84^{\circ}$ in $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}, 131.08^{\circ}$ in $\mathrm{Pb}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}, 128.34^{\circ}$ and $130.33^{\circ}$ in $\mathrm{Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$.

Keywords: Kentrolite, melanotekite, $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}, \mathrm{~Pb}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}, \mathrm{~Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$, crystal-structure, X-ray-diffraction, EMP-analysis

## INTRODUCTION

Kentrolite $\left(\mathrm{Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}\right)$ is a rare mineral and occurs mainly in $\mathrm{Mn}-$ and Pb -leading skarn ore deposits. It was found, i.e., in Tsumeb, Otjikoto (Namibia) and in Långban, Filipstad, Värmland, (Sweden).

Kentrolite is an orthorhombic sorosilicate with $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups with $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$-dimers aligned to [100]. The $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups are associated with edge-shared $\left(\mathrm{Mn}^{3+} \mathrm{O}_{6}\right)$ octahedra, which build an infinite octahedral chain parallel [001]. These octahedra are alternately trans and skew with respect to adjacent octahedra (Moore et al. 1991; Barbier and Lévy 1998), see Figure 1.

The linkage of octahedra chains in the kentrolite group can be related to other known crystal structures, i.e., the borax structure $\left[\mathrm{Na}\left(\mathrm{H}_{2} \mathrm{O}\right)_{4}\right]_{2}\left[\mathrm{~B}_{4} \mathrm{O}_{5}(\mathrm{OH})_{4}\right]$, with sodium as central atom in the octahedron. The octahedra chains in borax are bonded with hydrogen and $\mathrm{B}_{2} \mathrm{O}_{7}-\mathrm{BO}_{3}$ groups. The octahedra chain of kentrolite also closely resembles the infinite $\left[\mathrm{MnO}_{4}\right]$ chain of the synthetic phase CMS-X1 $\mathrm{Ca}_{3} \mathrm{Mn}_{2} \mathrm{O}_{2}\left(\mathrm{Si}_{4} \mathrm{O}_{12}\right)$, which was found next to piemontite (Anastasiou and Langer 1977).

[^0]The complete $\mathrm{Pb}_{2}\left(\mathrm{Mn}, \mathrm{Fe}_{2}\right)_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ solid-solution series was studied by Ito and Frondel (1966). The end-members with Cr , $\mathrm{Ga}, \mathrm{Sc}$, and In were synthesized by Ito and Frondel (1968) and Ito (1968).

The first crystal-structure model of natural kentrolite $\left(\mathrm{Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}\right)$ is given in space group $C 222_{1}$ based on Weissenberg photographs from Gabrielson (1961). Later, Ito and Frondel (1966) synthesized solid-solution series between the Mn and Fe end-member, $\mathrm{Pb}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$, named melanotekite. Lattice parameter refinement within the solid solution showed a linear relation with $X_{\mathrm{Fe}}$ based on powder-XRD data.

Gabelica-Robert and Tarte (1979) subsequently synthesized the known kentrolite structures and additional Ge -analogues and also structures with double substitution $2 \mathrm{M}^{3+} \rightarrow \mathrm{M}^{2+}+\mathrm{M}^{4+}$ with $\mathrm{M}^{2+}(\mathrm{Mg}, \mathrm{Co}, \mathrm{Ni}, \mathrm{Cu})$ and $\mathrm{M}^{4+}(\mathrm{Ti}, \mathrm{Sn})$. They found no common linear behavior of lattice parameters of these kentrolite endmembers based on the ionic radii (Shannon 1976) of the transition metals of the fourth period. In particular, kentrolite structures with $\mathrm{Mn}^{3+}$ and $\mathrm{Cu}^{2+}$ differ significantly in lattice parameters as expected from ionic radii. From IR and Raman spectroscopy, these authors suggested a lower symmetric space group than $C 222_{1}$, however without providing a structure solution.

Single-crystal diffraction study of a natural melanotekitekentrolite crystal with $X_{\mathrm{Mn}}=0.68$ was described by Moore et al. (1991) in space group Pbcn. This structure model is well described by Moore et al. (1991) and differs strongly from the previous one and is most likely the correct structure model for the kentrolite group because interatomic distances and angles are more believable. However, the authors noticed that the $6 \mathrm{~s}^{2} \mathrm{~Pb}^{2+}$ lone-pair cations are split asymmetrically in two positions with site occupation factors (SOF) $\mathrm{Pb} 1 \mathrm{SOF}=0.73$ and $\mathrm{Pb} 2 \mathrm{SOF}=$ 0.27 , but could not explain why. Werner and Müller-Buschbaum (1997) synthesized $\mathrm{Pb}_{2} \mathrm{In}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ in space group Pna2 ${ }_{1}$, what can be expressed as $P 2_{1} c n$, a non-centrosymmetric subgroup of Pbcn . This structure contains isotypic units of $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups and the same linkage with M -octahedra chains as the model of Moore et al. (1991) but no split of the Pb site and lack of an inversion center.

Barbier and Lévy (1998) synthesized the germanate analogue of melanotekite with the formula $\mathrm{Pb}_{2}\left(\mathrm{Fe}_{1.78}, \mathrm{Mg}_{0.11}, \mathrm{Ge}_{0.11}\right) \mathrm{Ge}_{2} \mathrm{O}_{9}$ in space group Pbcn and showed further that the structure is relatively flexible for solid solutions with Mg and Ge on the M sites ( $X_{\mathrm{Fe}}=0.89$ ), and for Ge on the T sites. They observed also a split of the Pb -site with $\mathrm{Pb} 1 \mathrm{SOF}=0.91$ and $\mathrm{Pb} 2 \mathrm{SOF}=0.09$. In principle all these works show that the Pb site complicates space group determination, structure solution and refinement, whereas only small changes occur in $\mathrm{T}_{2} \mathrm{O}_{7}$-group and the infinite $\left(\mathrm{M}^{3+} \mathrm{O}_{4}\right)$-chains.

Figure 1. Crystal structure of $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ in space group Pbcn , (a) projection from $\mathbf{a}$ on the $\mathbf{b}-\mathbf{c}$ plane, and $(\mathbf{b})$ from $\mathbf{c}$ on the a-b plane.

In general, the problem with the split Pb -site is observed in several other Pb -bearing phases, i.e., in Pb -hollandite, a split Pb site was found (Downs et al. 1995); in feldspar-(Pb), the split Pb site was observed as an effect of thermal treatment (Tribaudino et al. 1998). In phoenicochroite $\left[\mathrm{PbO}\left(\mathrm{CrO}_{4}\right)\right]$, no splitting in Pb site was observed however, lead atoms build $\left(\mathrm{Pb}_{2} \mathrm{O}\right)$-cluster chains with relatively short $\mathrm{Pb}-\mathrm{Pb}$ distances of $3.56 \AA$ (Morita and Toda 1984). Krivovichev and Burns (2001, 2002 and references therein) found $\left(\mathrm{Pb}_{4} \mathrm{O}\right)$-clusters in lead oxide chlorides. In contrast to strontium and barium, lead in the oxidation state $\mathrm{Pb}^{2+}$ can build a $6 \mathrm{~s}^{2}$ lone pair and is able to compensate for strain within the structure. Therefore $\mathrm{Pb}^{2+}$-cations must not necessarily be placed in a closed coordination polyhedron [see crystal structure of damaraite (Krivovichev and Burns 2001), with 6 different coordinated lead sites].

All these observations show clearly that lead atoms have a different chemical character than other isovalent elements with similar size. Here, we report first on the crystal structure of synthetic $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$. Then, we give crystal structures of kentrolite $\left(P 2_{1} 22_{1}\right)$ and melanotekite ( $P b c n$ ) based on single-crystal diffraction studies, and finally, we discuss structural differences within the kentrolite group.

## EXPERIMENTAL SETUP AND MICROPROBE ANALYSES

A list of synthesis conditions for the kentrolite isotypes with $\mathrm{Al}, \mathrm{Ga}, \mathrm{In}$, and the transition metals from the literature is summarized in Table 1. All phases were synthesized between 1 atm and 2 GPa and 450 and $4053{ }^{\circ} \mathrm{C}$. $\mathrm{CIF}^{1}$ is available via the web.

## High-pressure synthesis of $\mathbf{P b}_{\mathbf{2}} \mathbf{A l}_{2} \mathbf{S i}_{2} \mathbf{O}_{\mathbf{9}}$

At 1 atm pressure, the phase diagram of the ternary system $\mathrm{PbO}-\mathrm{Al}_{2} \mathrm{O}_{3}-\mathrm{SiO}_{2}$ (Chen et al. 2001) does not indicate the stability nor the existence of $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$;

however, two other phases, $\mathrm{Pb}_{4} \mathrm{Al}_{4} \mathrm{Si}_{5} \mathrm{O}_{20}$ and $\mathrm{Pb}_{4} \mathrm{Al}_{4} \mathrm{Si}_{3} \mathrm{O}_{16}$, are shown that have excess or lack of $\mathrm{SiO}_{2}$ compared to kentrolite-(Al). We obtained kentrolite-(Al) from high-pressure experiments at 2.0 GPa and $650^{\circ} \mathrm{C}$. In our experiment, which was originally aimed to synthesize zoisite- $(\mathrm{Pb})$, a mixture of $7.51 \mathrm{mg} \alpha-\mathrm{SiO}_{2}(99.99 \%)$, $19.509 \mathrm{mg} \mathrm{PbAl} \mathrm{O}_{4}$ (synthetic, from $\gamma-\mathrm{Al}_{2} \mathrm{O}_{3}$ and PbO by heating at $800^{\circ} \mathrm{C}$ in a corundum-crucible), and 4.464 mg PbO ( $99.99 \%$ ) was ground and homogenized in acetone. Thirty-five microliters of distilled $\mathrm{H}_{2} \mathrm{O}$ were injected in a Pt capsule (12 mm long and 3 mm in diameter), 25 mg of the mixture were added and the capsule sealed. The capsule was placed in a NaCl -graphite assembly. Pressure was set in an unloaded piston cylinder press to $2.0(1) \mathrm{GPa}$ and temperature kept constant at $650(5){ }^{\circ} \mathrm{C}$ for 6 days, controlled by a Ni-CrNi thermocouple. Details for the pistoncylinder experiment are given by Wunder and Melzer (2002).

## High-temperature synthesis of $\mathrm{Pb}_{2} \mathbf{M n}_{2} \mathrm{Si}_{2} \mathbf{O}_{9}$ and $\mathrm{Pb}_{2} \mathrm{Fe}_{2} \mathbf{S i}_{2} \mathrm{O}_{9}$

Suitable crystals of end-members $\mathrm{Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ and $\mathrm{Pb}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ were obtained by crystallization of PbO -enriched melt. We mixed the oxides $\mathrm{PbO}, \mathrm{Fe}_{2} \mathrm{O}_{3}$, and $\mathrm{SiO}_{2}$ in stoichiometric amounts with excess of PbO to compensate its volatilization and placed the melanotekite mixtures on platinum plates (for kentrolite we used $\mathrm{MnO}_{2}$ instead of $\mathrm{Fe}_{2} \mathrm{O}_{3}$ ). Mixtures were heated up to $1100{ }^{\circ} \mathrm{C}$ for complete melting. Temperature was reduced to $850(10)^{\circ} \mathrm{C}$ within an hour and held for two days. After that, samples were quenched in air.

## Microscopic observations

In contrast to melanotekite and kentrolite, which have strong orange-red and red colors, the Al-analogue appears colorless in transmitted light. Electron microprobe analyses (EMP) were performed on polished and carbon coated samples with a Cameca SX 50 microprobe using wavelength dispersive spectrometry (WDS) and the PAP correction program (Pouchou and Pichoir 1984). Acceleration voltage was 10 kV , beam current 15 to 20 nA , and beam diameter was $1 \mu \mathrm{~m}$. The following wavelengths and analyzator crystals were used: $\operatorname{Si} K \beta$ (TAP), Al $K \alpha$ (TAP), $\mathrm{Mn} K \alpha$ (PET), $\mathrm{Fe} K \alpha$ (LIF), and $\mathrm{Pb} M \alpha$ (PET). Standard for Si and Al was synthetic kyanite; for Fe and Mn we used pure metals. For Pb we started to use PbO and Pb -metal as standards. However, this resulted in large errors and implausible oxide sums. Therefore, we used the synthetitic kentrolite- $(\mathrm{Al})\left(\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}\right)$ itself as standard for Pb , assuming an ideal stoichiometry. The method was checked by analyzing other synthetic Pb -silicates margarite- $(\mathrm{Pb}) \mathrm{PbAl}_{4} \mathrm{Si}_{2} \mathrm{O}_{10}(\mathrm{OH})_{2}$, zoisite- $(\mathrm{Pb})$ $\mathrm{Pb}_{2} \mathrm{Al}_{3} \mathrm{Si}_{3} \mathrm{O}_{12}(\mathrm{OH})$, which occurred together with kentrolite in this high-pressure experiment and lawsonite- $(\mathrm{Pb}) \mathrm{PbAl}_{2}\left[(\mathrm{OH})_{2} / \mathrm{Si}_{2} \mathrm{O}_{7}\right] \cdot \mathrm{H}_{2} \mathrm{O}$ as well as plumbotsumite $\left[\mathrm{Pb}_{5} \mathrm{Si}_{4} \mathrm{O}_{8}(\mathrm{OH})_{10}\right]$ from other experiments synthesized at 4 GPa and $600^{\circ} \mathrm{C}$ (Table 2). The results indicate that Pb is still slightly higher than in the ideal formula, but satisfying for the purpose of our study because the results show that the Pb -position in the structure is completely occupied.

Synthetic kentrolite was found to be euhedral with small braunite $\left(\mathrm{Mn}_{7} \mathrm{SiO}_{12}\right)$ inclusions in a matrix with lead-orthosilicate $\left(\mathrm{Pb}_{2} \mathrm{SiO}_{4}\right)$ composition (Fig. 2). In contrast to kentrolite-(Al) and kentrolite, the crystal size of melanotekite was small and some crystals contain fine inclusions of hematite $\left(\mathrm{Fe}_{2} \mathrm{O}_{3}\right)$.

## Results

## $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$

Single, transparent, clear, idiomorphic, prismatic crystals, up to $150 \mu \mathrm{~m}$ length were obtained and used for single-crystal diffraction studies and microprobe analysis. Experimental details of the data collection for the structure determination are summarized in Table 3. The $\lambda / 2$-effect caused weak additional intensities and first we assumed a larger cell with doubled lattice
parameter. But the weak intensities were only present close to the center ( 000 ) and disappear with increasing n . In reciprocal space, we choose the larger cell, and sampled over all matching intensities of the orthorhombic cell with the parameters $a=$ $6.8981(7) \AA, b=10.6906(15) \AA$, and $c=9.7413(10) \AA$. Using this approach, weak intensities at the half of the reciprocal lattice were so rejected. But still some weak intensities caused by $\lambda / 2$-effect, remain on the chosen lattice. The data were not further corrected for $\lambda / 2$-effect.

To account for the strong absorption coefficient of Pb , we corrected the data with a spherical absorption model. Structure solution was done with direct methods, using the program SIR92 (Altomare et al. 1992). Statistical tests on the $|\mathrm{E}|$ values indicated strongly the existence of an inversion center. Space group determination suggested $P b c n$ with the best fit. Intensities, which do not fit with Pbcn and seem to be caused by $\lambda / 2$-effect (Table 4), were not used in our final structure model. Structure solutions and refinements (SHELXL-97 program; Sheldrick 1993) in possible subgroups of $P b c n, P 112_{1} / n, P 2_{1} / b 11, P 2_{1} c n, P b 2 n$, and $P \overline{1}$ were all done, but all of them were not using these intensities either and delivered negative $U_{\text {iso }}$ values. With respect to the work of Werner and Müller-Buschbaum (1997), we tried structure solution in space group $P 2{ }_{1} c n$, which converged with a $R_{1}$ of $13 \%$. Further structure refinement with weighting parameters, extinction, and anisotropic displacement factors, and a twinning matrix $(\overline{1} 00)(0 \overline{1} 0)(001)$ suggested from the Platon program

Figure 2. BSE-image shows euhedral kentrolite crystals with small braunite inclusions in a matrix with $\mathrm{Pb}_{2} \mathrm{SiO}_{4}$ composition.

(Spek 2005) yielded $2.4 \%$ and $w R 2$ for $R_{1}$ and $w R 2$, respectively. However, this structure refinement has negative $U_{\text {iso }}$ for more than 8 atoms, and we dismissed therefore $P 2_{1} \mathrm{Cn}$ as possible space group for $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$.

The final structure was solved in space group Pbcn. All atom positions were found with $R_{1}=5.35 \%$. The refinement of the weighting and extinction parameters dropped $R_{1}$ to $3.50 \%$. The refinement of the anisotropic displacement factors further reduced $R_{1}$ to $2.23 \%$. Two positions with residual electron density ( 2.48 and 2.18 ) at a distance of 0.83 and $0.89 \AA$ from the Pb site were found. Fourier-mappings indicate no strong irregularities of the Pb site (Fig. 3) compared with Pb sites of melanotekite and kentrolite. The refined atomic coordinates and equivalent isotropic and anisotropic displacement parameters, as well as selected interatomic distances and angles are given in Tables 5-7.

## $\mathbf{P b}_{\mathbf{2}} \mathbf{M n}_{2} \mathbf{S i}_{2} \mathbf{O}_{\mathbf{9}}$

A large $(150 \times 200 \times 80 \mu \mathrm{~m})$ red crystal of kentrolite was used for structure solution. The $\lambda / 2$-effect also occurs as in $\mathrm{Pb}_{2} \mathrm{Al}_{2}$. $\mathrm{Si}_{2} \mathrm{O}_{9}$. Lattice parameters were refined on 6934 reflections and yield $a=7.0079(4) \AA, b=11.0665(5) \AA$, and $c=9.9634(5) ~ \AA$. An analytical absorption correction was applied. Statistical tests on

TABLE 4. Systematic absence violations caused by $\lambda / 2$-effect for $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$

| Regular strong intensities on the basisof $(045) 100 \%$ |  | Observed (hkl) not allowed in Pben |  |
| :---: | :---: | :---: | :---: |
| (202) | 64-70\% | (101) | 0.83\% |
| (062) | 22-23\% | (0 31 ) | 0.26\% |
| (280) | 24\% | (140) | 0.16\% |
| (060) | 22\% | (030) | 0.29\% |
| (0 010 ) $\dagger$ | 61\% | (0 05 )* | 0.22\% |
| (0 100) | n.d. | (050) | 0.36\% |

* Intensity was earlier observed by Glasser (1967) and Moore et al. (1991).
† Intensity was mentioned and omitted in the structure solution by Barbier and Lévy (1998).
the $|\mathrm{E}|$ values indicated strongly the lack of an inversion center. In contrast to melanotekite and kentrolite-(Al), the extinction law for space group $P b c n$ is violated for $(0 k l)$ with $k=2 \mathrm{n}+1$, $(h 0 l)$ with $l=2 \mathrm{n}+1$, and ( $h k 0$ ) with $h+k=2 \mathrm{n}+1$.

Only ( $h 00$ ) with $h=2 \mathrm{n}+1$ and ( 001 ) with $l=2 \mathrm{n}+1$ extinctions were found and so space group $P 2_{1} 22_{1}$ was chosen $[I / \sigma(I)<2.37]$. Structure solution in this space group results in $R=7.74 \%$.

When we use a higher cutoff $I / \sigma(I)<6$ for space group determination, we obtain the kentrolite space group $C 222_{1}$ determined earlier by Gabrielson (1961). However, structure solution and refinement in this space group results in an unrealistic structure

Figure 3. Fourier-mappings ( $F_{\text {obs }}$ ) of the Pb sites in kentrolite-(Al), melanotekite, and kentrolite illustrating differences in electron density ( 16 contour levels with $20 \mathrm{e} / \AA^{3}$ ).
model, similar to the one given by Gabrielson (1961), which was characterized by strongly distorted polyhedra, very large thermal-vibration parameters, and high $R$-values. Therefore, this model was not considered.

Based on the lower symmetry of space group $P 2_{1} 22_{1}$ two Pb sites, three Mn sites, two Si sites, and ten O sites were located. Additionally, two different residual electron densities of $20 \mathrm{e} / \AA^{3}$ next to Pb 1 and $35 \mathrm{e} / \AA^{3}$ next to Pb 3 were found. We split the two positions in Pb 1 and Pb 2 with $\mathrm{SOF}=0.72$ and $0.28, \mathrm{~Pb} 3$ and Pb 4 with $\mathrm{SOF}=0.65$ and 0.35 , respectively. Structure refinement suggested twinning, and $R_{\mathrm{w}}$ was three times higher than $R_{1}$. By the use of the Le Page algorithm (Program Platon, Spek 2005), space group Pbcn was indicated with an origin shift of ( 00.2498 -0.25 ) for all atoms with exception of the sites $\mathrm{Pb} 1, \mathrm{~Pb} 2, \mathrm{~Pb} 3$, and Pb 4 . The structure was further refined in twin mode (inversion) with twin fraction 0.42 resulting in $R_{1}=0.033$ and $R_{\mathrm{w}}=0.086$. Data of the structure and interatomic distances and bond angles are given in Tables 8, 9, and 10.

## $\mathbf{P b}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$

A small $(40 \times 50 \times 30 \mu \mathrm{~m})$ orange-red crystal of melanotekite was used for single-crystal diffraction studies. No additional peaks caused by $\lambda / 2$-effect were observed. Lattice parameters were refined on 1298 reflections and yield to $a=6.9788$ (6) $\AA, b$ $=11.0164(11) \AA$, and $c=10.0881(9) \AA$. An analytical absorption correction was applied.

Statistical tests on the $|\mathrm{E}|$ values indicated strongly the existence of an inversion center, and extinctions were consistent with space group $P b c n$ as in $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$. The $R$-value for this solution was $12.42 \%$. All atoms were found similar as in $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$, however residual electron density of $45 \mathrm{e} / \AA^{3}$ was located next

to the Pb 1 -site. On that position we added a Pb 2 -atom with SOF 0.3 and reduced the SOF of Pb 1 to 0.7 , following the method used by Moore et al. (1991). The refinement of the anisotropic displacement factors and weighting parameters reduced agreement values to $R_{1}=4.28 \%$ and $R_{\mathrm{w}}=8.56 \%$. Additional refinements of the $\mathrm{Pb}-\mathrm{SOF}$ with constraints between Pb 1 and Pb 2 did not significantly improve $R$-values and often resulted in negative anisotropic displacement factors for O 1 and Pb 2 . The refined

atomic coordinates and equivalent isotropic and anisotropic displacement parameters, as well as selected interatomic distances and angles are given in Tables 11-13.

## DISCUSSION

## Lattice parameter

The lattice parameters of $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ are very small compared to other kentrolite isotypes and its cell volume is the smallest ever observed in the kentrolite structure family. The lattice parameters of the $\mathrm{Al}, \mathrm{Ga}$, and In end-members are a linear function of their ionic radii (Fig. 4). Unit-cell volume of kentrolite and melanotekite show the same trend when sixfoldcoordinated $\mathrm{Mn}^{3+}$ and $\mathrm{Fe}^{3+}$ is present in high spin mode with ionic radii of $0.645 \AA$ (Shannon 1976). Lattice parameters $a$ and $b$ are slightly higher in kentrolite, whereas $c$ is obviously shorter than in melanotekite.

## Space groups of the kentrolite structure family

The structure model of melanotekite and kentrolite-(Al) in space group $P b c n$ is in good agreement with the structure model of Moore et al. (1991).

The observed $\lambda / 2$-effect for kentrolite-(Al) causes further weak intensities $[(005),(101),(031)]$, which violate the extinction law of Pbcn and makes space group determination for kentrolite structures in general more complicated. Based on our results for kentrolite-(Al) and kentrolite, we speculate that $\lambda / 2-$ effect of the strong (0010) reflection is most likely the reason for the (005)-reflection earlier observed by Glasser (1967) and Moore et al. (1991).

In the structure of the analyzed kentrolite crystal, lead atoms do not conform to space group Pbcn as the rest of the structure (see electron density maps in Fig. 5). As a result, glide planes, inversion center and $2_{1}$ screw axis along $\mathbf{b}$ are lost. Therefore, $P 2_{1} 22_{1}$ is the most reasonable space group for our synthetic kentrolite crystals and not $C 222_{1}$ as suggested by Gabrielson (1961).

There are three space groups $P b c n, P 2_{1} 22_{1}$, and $P 2_{1} c n$ in the kentrolite structure family. Melanotekite and kentrolite-(Al), kentrolite, and kentrolite-(In) have a different cation on the M site and were obtained by different synthesis conditions. The In end-

member with large M-octahedra and lattice volume was obtained from high-temperature experiments, whereas the Al end-member with small M-octahedra and small lattice volume was obtained by high-pressure experiments. We generally assume that lattice volume of kentrolite increases with temperature and that could result in changes of the Pb site, which might influence symmetry. The observed split of Pb sites in the kentrolite structure family is possibly a result of thermal treatment similar as in feldspar $-(\mathrm{Pb})$ (Tribaudino et al. 1998). Based on the split Pb sites and the observed pseudo symmetry to $P b c n$, we speculate that with increase in temperature at least one phase transition occurs in kentrolite, with change of space group from $P 2_{1} 22_{1}$ to $P b c n$.

## Structure

The linkage of T- and M-polyhedra of the refined crystal structures is generally identical with the structure described by Moore et al. (1991), Barbier and Lévy (1998), and Werner and Müller-Buschbaum (1997). To compare the structures visually, the Figure 6 shows a projection along $\mathbf{c}$ on the a-b plane of each end-member. From this view, structures are nearly identical with exception of the lead position. In the kentrolite structure, two different and split Pb sites are laterally linked to the octahedral chain and alternate along the $\mathbf{b}$-axes.

Figure 4. Changes in lattice parameters as a function of ionic radii (Shannon 1976) of trivalent cations ( $\mathrm{Fe}, \mathrm{Mn}$ in high spin) on the M-positions in sixfold coordination in kentrolite isotypes. Open squares represent data for melanotekite and kentrolite (this study); filled squares represent the kentrolite isotypes of Al , In , and $\mathrm{Ga}(\mathrm{Al}=$ this study; In = Werner and Müller-Buschbaum 1997; $\mathrm{Ga}=$ Gabelica-Robert and Tarte 1979) open triangles represent Cr and Sc -isotypes (Gabelica-Robert and Tarte 1979).

## Octahedra chain

Kinked octahedra chains of melanotekite, kentrolite, and kentrolite-(Al) are very similar. Only small differences occur in M2-M2-M2 angles within the chain. The smaller octahedra chain of the Al-isotype and kentrolite is more stretched than in the In-isotype (Al2-Al2-Al2 $=114.4^{\circ}$, and $\mathrm{Mn} 1-\mathrm{Mn} 2-\mathrm{Mn} 1=$ $114.5^{\circ}, \mathrm{Fe} 2-\mathrm{Fe} 2-\mathrm{Fe} 2=112.81^{\circ}$, In2-In2-In2 $=110.2^{\circ}$, see Fig. 7). The decrease in M2-M2-M2 angle and kinking of M2-M1-M2 sequence is linked to the size of each octahedron and the fixed distance $\mathrm{O} 1-\mathrm{O} 2$, the edge of the T 1 .

In kentrolite-(Al) the $\mathrm{All-Al2-All}=180.00^{\circ}$, melanotekite $\mathrm{Fe} 2-\mathrm{Fe} 1-\mathrm{Fe} 2=179.98^{\circ}$, and kentrolite $\mathrm{Mn} 1-\mathrm{Mn} 3-\mathrm{Mn} 2=$ $179.54^{\circ}$. The octahedra volumes and edges $\mathrm{O} 3-\mathrm{O} 3$ in $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ $(2.87 \AA)$ and $\mathrm{Pb}_{2} \mathrm{Fe}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}(3.05 \AA)$ and $07-\mathrm{O} 7$ and $\mathrm{O} 4-\mathrm{O} 4$ in $\mathrm{Pb}_{2} \mathrm{Mn}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ (3.07 and $3.09 \AA$, respectively) increase in the order $\mathrm{Al}, \mathrm{Fe}$, and Mn (Table 14).

Beyond the size of M-octahedra, there are no pronounced differences in the M1 and M2 octahedra of kentrolite-(Al) and
melanotekite. The ratio of the bond-length M1-O5, M1-O1, and M1-O2 is 0.97:1.00:1.04 in kentrolite-(Al) and 0.98:1.00:1.04 in melanotekite. The ratio of the bond-length M2-O5, M2-O3, and M2-O1 is 0.93:1.00:1.01 in kentrolite-(Al) and 0.94:1.00:1.01 in melanotekite.

Some significant differences are noted for kentrolite. The ratio of the bond-length is for M1-O9, M1-O7, and M1-O6 0.90:1.00:1.00 and for M2-O1, M2-O8, and M2-O4 0.90:1.00:1.01. The octahedral sites M1 and M2 in kentrolite are tetragonally $(2+4)$-distorted, what is commonly observed for $\mathrm{Mn}^{3+} \mathrm{O}_{6}$ octahedra (Jahn-Teller effect). The M3 octahedron behaves differently. Here, we have two short, two intermediate, and two long M3-O bonds with the ratio 0.96:1.00:1.11 (see Table 10 and Figs. 7c and 7d). Mn1-O9 and Mn2-(O1) are perpendicular to $\mathbf{b}$ crystallographic axis and roughly parallel to $\mathbf{c}$, therefore $\mathbf{c}$ in kentrolite is shortened compared to that in melanotekite, whereas $\mathbf{a}$ and $\mathbf{b}$ are stretched due to the increased equatorial bond lengths Mn1-O7, Mn1-O6, Mn2-O4, Mn2-O8, Mn3-O5,

Figure 6. Crystal structure of (a) kentrolite-(Al), (b) melanotekite, and (c) kentrolite, projected from $\mathbf{c}$ on the a-b plane. Lead positions with high site occupation factor (SOF) are shown as black and gray filled circles. Split lead positions with low SOF are shown as small white or gray filled circles.

and Mn3-O3. Octahedra distortions are $\Delta_{\mathrm{M} 1}=0.003, \Delta_{\mathrm{M} 2}=0.003$, and $\Delta_{M 3}=0.004$ with $\Delta_{M}=1 / 6 \Sigma\left[\left(\mathrm{~L}_{\mathrm{i}}-\mathrm{L}_{\mathrm{m}}\right) / \mathrm{L}_{\mathrm{m}}\right]^{2}\left(\mathrm{~L}_{\mathrm{i}}\right.$ is an individual

Figure 7. Differences in octahedral chain in (a) kentrolite-(Al) compared to (b) kentrolite-(In). Octahedra chain in kentrolite-(Al) is stretched. Black dots represent $\mathrm{Al1}$ and Al 2 atoms in kentrolite-(Al), respectively, In1 and In2 atoms in Kentrolite-(In). Differences in Moctahedra of (c) melanotekite and (d) kentrolite is shown with bondlength. The shortest bonds of each octahedon are in gray.
$\mathrm{Mn}^{3+}-\mathrm{O}$ bond-length and $\mathrm{L}_{\mathrm{m}}$ is the mean $\mathrm{Mn}^{3+}$ - O bond-length of the corresponding octahedron, see Table 10). The $\Delta_{\mathrm{M} 3}$ value fits well with the dependence of mean distance on distortion given by Shannon et al. (1975) and Burns et al. (1994). However, $\Delta_{\mathrm{M} 1}$ and $\Delta_{\mathrm{M} 2}$ values do not conform to these trends.

In Figure 8, we compare the sizes of the M-octahedra in the Al- and In-isotypes with the sizes of the simple oxides $\left(\mathrm{M}_{2} \mathrm{O}_{3}\right)$ of the third group of the periodic table of the elements. Both M1 and M2-octahedra of the A1-isotype are larger than in the corresponding $\alpha-\mathrm{Al}_{2} \mathrm{O}_{3}$, and both octahedra of the In-isotype are smaller than in $\mathrm{In}_{2} \mathrm{O}_{3}$. If a solid solution between these isotypes or with the Ga-isotype exists, the M1-site is most likely preferred by atoms with larger ionic radii and the M2-site by those with smaller ionic radii.

## (PbMO)-cluster

In melanotekite and kentrolite-(Al) the atom closest to Pb is O 5 and in kentrolite it is O 9 and O 1 . Within the octahedra, M1-O5 and M2-O5 distances are also much smaller than the other octahedral distances in melanotekite. In kentrolite, distances Mn1-O9, $\mathrm{Mn} 2-\mathrm{O} 1, \mathrm{Mn} 3-\mathrm{O} 9$, and Mn3-O1 behave in the same way.

The O 5 atom in kentrolite-(Al) and melanotekite, and also the O 1 and O 9 atoms in kentrolite are therefore more strongly bonded by Pb and the M sites than any other O atom in the kentrolite structure. For melanotekite and kentrolite-(Al), the O5-atom is fourfold-coordinated by two $\mathrm{Pb}^{2+}$ and two $\mathrm{Fe}^{3+}$ cations, and O5 is located in a stretched tetrahedron. The same applies to kentrolite for atoms O1 and O9. The tetrahedra are linked with each other over all vertices and build a 3D-network. In Figure 9, the melanotekite structure is plotted with $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups and the ( PbFeO )-cluster projected from a on the b-c plane. From this view $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups are located in the middle of $(\mathrm{PbFeO})$-cluster " 6 -er" rings with ( $\mathrm{Fe}, \mathrm{Fe}, \mathrm{Fe}, \mathrm{Pb}, \mathrm{Fe}, \mathrm{Pb}$ ) linkage sequence. The $\mathrm{Fe}-\mathrm{O}$ and $\mathrm{Pb}-\mathrm{O}$ bonds, which influence the position of the $\mathrm{Si}_{2} \mathrm{O}_{7}-$ group, are drawn in as solid black and white lines. The fact that two short $\mathrm{Fe} 1-\mathrm{O} 5$ and two short $\mathrm{Fe} 2-\mathrm{O} 5$ distances occur results in weaker $\mathrm{Fe}-\mathrm{O}$ bonds to oxygen atoms of the $\mathrm{Si}_{2} \mathrm{O}_{7}$-group, which might cause the high-spin mode of $\mathrm{Fe}^{3+}$ and $\mathrm{Mn}^{3+}$.

## $\mathrm{Si}_{2} \mathbf{O}_{7}$-group

The oxygen positions and symmetry of the $\mathrm{Si}_{2} \mathrm{O}_{7}$-group are influenced strongly by M2, because the O3-O3 distance of the opposing tetrahedron is also an edge of one M2 octahedron. When the size of the octahedra increases, the angle Si1-O4-Si1 will also increase. The small octahedra in $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ causes a Sil-O4-Sil angle of $129.84^{\circ}$ for the $\mathrm{Si}_{2} \mathrm{O}_{7}$-group; this angle is $131.08^{\circ}$ in melanotekite. In kentrolite two different $\mathrm{Si}_{2} \mathrm{O}_{7}$ groups are present with angles $\mathrm{Si} 1-\mathrm{O} 2-\mathrm{Sil}=128.34^{\circ}$ and $\mathrm{Si} 2-\mathrm{O}(10)-$ $\mathrm{Si} 2=130.33^{\circ}$.

The corresponding Si1-O6-Si1 angle of the $\mathrm{Si}_{2} \mathrm{O}_{7}$-group of $\mathrm{Pb}_{2} \mathrm{In}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ (Werner and Müller-Buschbaum 1997) is about $134^{\circ}$. The obtained Si-O-Si angles in this work are in total agreement with IR and Raman studies on the kentrolite group by Gabelica-

Figure 8. Comparison of mean $\mathrm{M}-\mathrm{O}$ distances of $\mathrm{M}^{3+}(\mathrm{M}=\mathrm{Al}, \mathrm{Ga}$, In, Tl ) octahedra in $\mathrm{Pb}_{2} \mathrm{M}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$ and $\mathrm{M}_{2} \mathrm{O}_{3}$ as a function of ionic radii (Shannon 1976).

Robert and Tarte (1979). In addition to that they found only one $v_{\text {sym. }}$ (SiOSi)-frequency at $696 \mathrm{~cm}^{-1}$ in melanotekite but two $v_{\text {sym. }}$ (SiOSi)-frequencies at $701 \mathrm{~cm}^{-1}$ and $694 \mathrm{~cm}^{-1}$ in synthetic kentrolite. This can be explained by two different $\mathrm{Si}_{2} \mathrm{O}_{7}$-groups in the kentrolite structure model in space group $P 2_{1} 22_{1}$.

## $\mathbf{P b}$ site

As shown in the Fourier maps for melanotekite and kentrolite, electron density distribution at the Pb site is very inhomogeneous. This results in additional electron densities of 20-40 e/ $\AA^{3}, 0.5-0.7 \AA$ away from the Pb site, conspicuous in the structure refinement procedure. The split into two Pb sites in melanotekite and kentrolite reduce residual electron densities below 3. In the refinement of both split Pb sites, their displacement spheres interpenetrate because they are very close to each other. In melanotekite, the distance between the split Pb site is $\mathrm{Pb} 1-\mathrm{Pb} 2$ $=0.45 \AA$, and in kentrolite distances are $\mathrm{Pb} 1-\mathrm{Pb} 2=0.11 \AA$, $\mathrm{Pb} 3-\mathrm{Pb} 4=0.35 \AA$. The interpenetration can result in erroneous thermal-vibration parameters for the split positions and might influence also other atoms.

The lead position in kentrolite-(Al) can be compared with the lead position in massicot $(\mathrm{PbO})$. In $\mathrm{Pb}_{2} \mathrm{Al}_{2} \mathrm{Si}_{2} \mathrm{O}_{9}$, lead has four next O -atoms with $\mathrm{Pb}-\mathrm{O}$ distances of $2.37-2.47 \AA$ on one side and three further oxygen atoms on the other side with $\mathrm{Pb}-\mathrm{O}$ distances of $2.95-3.06 \AA$. The lone electron pair of $\mathrm{Pb}^{2+}$ is invisible in the electron density maps. However, it is thought to lie along the $\mathrm{Pb}-\mathrm{O} 5$ vector in in kentrolite-( Al ) and melanotekite and along the $\mathrm{Pb}-\mathrm{O} 1$ or $\mathrm{Pb}-\mathrm{O} 9$ vector in kentrolite, respectively.

Bond valence calculations for Pb site show that this position is deficient in bond valence ( $\mathrm{s}=1.71$, instead of 2.00). Atom O 3 , which is also influenced by the Pb site is also somewhat low in bond valence ( $\mathrm{s}=1.76$, instead of 2.00). In melanotekite,

FIGURE 9. Projection of the melanotekite structure from a on the b-c plane. ( PbFe )O-cluster with O 5 as central atom builds a 3D-network. The $\mathrm{Si}_{2} \mathrm{O}_{7^{-}}$group is placed in cavities of the cluster-network. Additional Fe-O and $\mathrm{Pb}-\mathrm{O}$ bonds are shown as solid black and white lines, respectively.

Figure 10. [ PbFeO$]$-cluster displacement by split Pb site.

Pb 1 has four next neighbors as kentrolite-( Al ) and is placed between two octahedral chains, bonded by two O 5 atoms with same strength. The split partner Pb 2 is shifted toward one of these O 5 atoms and has in total one very short bond with O 5 and four intermediate bonds with O 3 and O 2 . The split of the lead position can also described as a stretching of $(\mathrm{PbFeO})$-clusters (Fig. 10). In kentrolite, Pb 1 is bonded with four oxygen atoms (O1, O1, O3, and O4), and it is rotated toward O3. The split partner Pb 2 is slightly shifted between O 3 and O 1 similar to the Pb 2 in melanotekite. Pb 3 and Pb 4 behave differently. Pb 3 is very strongly bonded to O 9 and has in total three next nearest oxygen neighbors with O 5 and O 7 . The split partner Pb 4 has five next-nearest O neighbors O 9 and two times O 5 and $\mathrm{O} 7 . \mathrm{Pb} 4$ is more symmetrically placed between the two O 5 and O 7 atoms and shifted away from O9.

## ACKNOWLEDGMENTS

This work was supported by the DFG, Project FR 557/18. We thank Marina Borowski and Elisabeth Irran (Anorganische Chemie, TU-Berlin, Germany) for their support at the single-crystal diffractometer as well as François Galbert (ZELMI, TU-Berlin, Germany) for his help at the microprobe.
